1. INTRODUCTION

Contrast agents are indispensable in the practice of radiology. Significant improvements in their composition during the past few decades have made them safer and better tolerated, as evidenced by their use in vast numbers of examinations, often in severely ill patients. Nonetheless, risks associated with contrast agents have not been eliminated, and adverse reactions of varying degree continue to occur. Consequently, it is imperative for anybody administering contrast agents to be intimately familiar with the characteristics, indications, and potential side effects of these agents. They must be able to recognize adverse reactions promptly and treat them effectively and rapidly. This tutorial is designed to help residents and practicing physicians utilize contrast agents in a manner that maximizes the safety of their patients. The information reflects policies and practices currently in use in the Radiology Department of the University of Wisconsin. The use of contrast agents should be determined on an individual basis according to the clinical circumstances of each patient. The contents of this tutorial do not guarantee that contrast agents can be used safely in any individual situation, for the decision to use a contrast agent must be made according to the best judgment of the physician in charge of the examination.

2. PHARMACOLOGY OF CONTRAST AGENTS

All intravascular iodinated contrast agents are based on a tri-iodinated benzene ring. Three primary forms exist:

High-osmolar contrast media (HOCM) are the oldest agents. They are relatively inexpensive, but their utility is limited. They are monomers (single benzene ring) that ionize in solution with a valence of -1. Their cation is either sodium or meglumine.

A major advance was the development of nonionic compounds. They are monomers that dissolve in water but do not dissociate. Hence, with fewer particles in solution, they are designated low-osmolar contrast media (LOCM).

The most recent class of agents is dimers that consist of a molecule with two benzene rings (again, each with 3 iodine atoms) that does not dissociate in water (nonionic). These compounds are designated iso-osmolar contrast media (IOCM).

The toxicity of contrast agents decreases as osmolality approaches that of serum. This has been accomplished by developing nonionizing compounds and then combining two monomers to form a dimer.

Representative osmolalities are:

Serum:	290 mosm/kg H ₂ O
HOCM: Ionic monomer: diatrizoate:	1570 mosm/kg H ₂ O
LOCM: Nonionic monomer: iohexol 240 (Omnipaque):	518 mosm/kg H ₂ O *
LOCM: Nonionic monomer: iohexol 300 (Omnipaque):	672 mosm/kg H ₂ O *
IOCM: Nonionic dimer: iodixanol 320 (Visipaque):	290 mosm/kg H ₂ O *

* Agents presently used at the University of Wisconsin Hospital and Clinics.

Since the purpose of these agents is to deliver iodine in sufficient concentration for imaging, the ratio of iodine atoms to particles in solution becomes important. Ratios are:

HOCM—.5
LOCM—3.0
IOCM —6.0

Additional modifications that have reduced toxicity include the following: adding calcium ions (reduces cardiac toxicity), establishing a neutral pH (low pH predisposes to vasodilatation), and altering number and distribution of —OH ions (decreases neural toxicity).

Currently used iodinated agents are cleared almost completely by glomerular filtration. With reduced renal function, there is vicarious excretion primarily in bile and through the bowel. Circulatory half life is 1–2 hours, assuming normal renal function.

3. METHODS OF CATEGORIZING CONTRAST REACTIONS

There are two useful ways to approach contrast reactions. One is to categorize them according to their severity. This method has immediate clinical relevance when reactions occur and provides a framework for determining an appropriate course of treatment. The other approach is to analyze them according to the type of adverse reaction. This is important to understand the mechanisms of reactions.

A. SEVERITY: The American College of Radiology has divided adverse reactions to contrast agents into the following categories:

Mild

Signs and symptoms appear self-limited without evidence of progression

Nausea, vomiting	Altered taste	Sweats
Cough	Itching	Rash, hives
Warmth (heat)	Pallor	Nasal stuffiness
Headache	Flushing	Swelling: eyes, face
Dizziness	Chills	Anxiety
Shaking		

Treatment: Observation and reassurance. Usually no intervention or medication is required; however, these reactions may progress into a more severe category.

Moderate

Reactions which require treatment but are not immediately lifethreatening

Tachycardia/bradycardia	Hypotension	Bronchospasm, wheezing
Hypertension	Dyspnea	Laryngeal edema
Pronounced cutaneous reaction	Pulmonary edema	

Treatment: Prompt treatment with close observation

Severe

Life-threatening with more severe signs or symptoms including:

Laryngeal edema (severe or progressive)		
Profound hypotension	Unresponsiveness	
Convulsions	Clinically manifest arrhythmias	Cardiopulmonary arrest

Treatment: Immediate treatment. Usually requires hospitalization.

Fortunately, most reactions are classified as mild. Within this category, itching, flushing, hives, nasal congestion, and swelling about the eyes and face are common. Nausea and vomiting have become less common with the use of low osmolar and iso-osmolar agents. Among the moderate reactions, bronchospasm and laryngeal edema are encountered most frequently; patients must also be monitored carefully for changes in cardiac rate and blood pressure. Severe reactions, while infrequent, can rapidly escalate to a life-threatening situation.

Delayed Contrast Reactions

Delayed contrast reactions can occur anywhere from 3 hours to 7 days following the administration of contrast. Since patients are generally discharged from the radiology department within 30 minutes of contrast administration, these reactions are rarely observed by the radiologist supervising the contrast administration. These events are often not brought to the attention of the radiologist since the delayed event may not be ascribed to the contrast media and these events are often self-limited. Regardless, it is important for anyone administering intravenous contrast media to be aware of delayed reactions.

With the exception of contrast-induced nephropathy, the more common reactions include a cutaneous xanthem, pruritis without urticaria, nausea, vomiting, drowsiness, and headache. While cardiopulmonary arrest has been reported, it is probably not related to newer contrast agents. Cutaneous reactions are the most frequent form of delayed contrast reaction with a reported incidence of 0.5-9%.

Cutaneous reactions vary in size and presentation but are usually pruritic. For the most part, these reactions are self-limited and symptoms can be treated with corticosteroid creams. Rare cases may progress to become severe, some resembling Stevens-Johnson syndrome or a cutaneous vasculitis. Consultation with a dermatologist is appropriate for delayed cutaneous reactions.

Delayed cutaneous reactions are more common in patients who have had a previous contrast reaction and those who have been treated within the past 2 years, or are currently being treated with interleukin-2 (IL-2). Due to this association, the University of Wisconsin Hospitals and Clinics screens patients for a history of IL-2 therapy.

B. MECHANISM

- Anaphylactoid
- Nonanaphylactoid
 - Chemotoxic – organ-specific
 - Nephrotoxicity
 - Cardiovascular toxicity
 - Neurotoxicity
 - Vasovagal

4. ANAPHYLACTOID REACTIONS

Pathophysiology

Anaphylactic reactions are events initiated when an allergen and IgE combine to induce mast cells to release chemical mediators. Mast cells originate from bone marrow precursors and develop in the organs in which they come to reside. Principal locations are the skin, respiratory tract, GI tract, and blood vessels.

Allergen-specific IgE is bound on the surface of mast cells. The allergen-IgE complex activates the mast cell and induces it to release histamine as well as other mediators.

Histamine binds to specific receptor sites. H1 receptors are found in endothelial and smooth muscle cells and in the central nervous system. H2 receptors are in gastric parietal cells and in inflammatory cells.

The nature of an anaphylactic reaction depends upon the location where it occurs. In the skin, vasodilatation produces urticaria and erythema. In mucosa, vasodilatation produces nasal congestion and laryngeal edema. In the respiratory tract, smooth muscle contraction produces bronchospasm. In peripheral vessels, vasodilatation produces hypotension and shock. Gastrointestinal reactions include nausea, vomiting, diarrhea, and cramps.

Anaphylactoid reactions are identical to anaphylactic reactions in their manifestations, but they are not initiated by an allergen-IgE complex. Indeed the pathway by which the mast cells become stimulated has not yet been clarified. Acute contrast reactions are included in this group.

The distinction between anaphylactic and anaphylactoid reactions is subtle, but it has certain important implications for the use of iodinated contrast:

1. A reaction can occur even the first time contrast is administered.
2. The severity of a reaction is not dose-related; therefore a test dose is of no value.

3. The occurrence of a contrast reaction does not necessarily mean that it will occur again (although of course the risk is greater that it may).
4. Even though the circulating contrast is systemic, the nature of the response is variable. More than one type of reaction may occur simultaneously.

As with anaphylactic reactions, certain risk factors make patients more susceptible to iodinated contrast (anaphylactoid) reactions:

1. Allergic asthma
2. Drug allergies
3. Food allergies
4. Prior reactions to contrast

Treatment of Anaphylactoid Reactions

Anaphylactoid reactions usually occur soon after contrast is administered. They are variable in duration and severity. They may occur abruptly and progress rapidly. Successful management of these events depends upon early recognition, prompt and accurate assessment, and preparedness. Because significant reactions do not occur often, it is necessary to review them frequently enough so that basic knowledge and management priorities remain current and fresh.

It is of utmost importance that medications and equipment be promptly available. An emergency box or cart should be in the immediate vicinity.

Preferably it should be sealed (not locked) so that it will be intact when needed. It must be periodically inspected (and recorded and signed on a check-off log) to insure that it is fully stocked and that none of its contents have expired. A list of medications, indications, and directions for their use and a list of emergency phone numbers should be prominently displayed. A stethoscope and blood

pressure cuff of sufficient quality for reliable clinical use should be included. There should be a bag of isotonic IV solution (normal saline or Ringer's solution) with IV tubing. An appropriate selection of needles and syringes and everything else needed to draw up medications or start additional IVs should be available. An Ambu bag™ with a proper assortment of masks, laryngoscopes with endotracheal tubes, and airways should be included. There should be a flashlight and tongue depressors. An oxygen tank and tubing should be close at hand. A clipboard with paper for flow sheets is very helpful. Additional equipment may also be necessary in your institution. All policies and procedures should be dated and periodically reviewed.

In the University of Wisconsin Hospital and Clinics, an emergency cart is maintained in the central control area of the CT complex. On the top of the cart, laminated in plastic, are lists of all of the drugs on the cart together with their adult and pediatric dose schedules. Within the cart are two sealed packages, one a respiratory kit and the other a drug kit, both with expiration dates posted on them. The drug kit is prepared by the pharmacy. The cart itself is closed (not locked) with a numbered seal. Every day, a designated nurse in CT checks the emergency cart and on an initialed and dated check-off log writes the known expiration date of the two kits inside and the number on the seal.

Verifying that the number on the seal is the same as the day before assures that the cart has remained intact. This system also permits a daily review of forthcoming expiration dates. If either the respiratory kit or the drug kit is used, it

is repacked with a new expiration date, and the cart is closed with a new numbered seal.

When summoned to assess a patient who may be having an adverse reaction, you must be able to act quickly, purposefully, and effectively. Ascertain from the technologist or nurse what the problem is. Speak to the patient to obtain additional information and determine how he/she responds. Consult information on pertinent medical history (this should be obtained before the contrast infusion is started). Immediately stop the contrast infusion, hook up isotonic IV fluids, and open the IV wide. Obtain vital signs. Check the airway and breathing. Listen to the lungs. Check skin color, temperature, and dryness. Do not hesitate to administer oxygen by mask (6–10 liters/min), elevate the patient's legs for hypotension, or start additional IVs as appropriate.

It has long been recognized that **anxiety** plays a role in evoking and potentiating contrast reactions. Therefore, your behavior and conduct become important factors in your ability to successfully manage the patient. You must maintain and display an unruffled, orderly, deliberate, capable, and effective demeanor, one that elicits confidence and promotes a sense of well-being in the patient. These same qualities are also important in coordinating the activities of staff members assisting you. You must be able to take charge, assign tasks, monitor activities, reassess the patient, and make effective decisions as circumstances change.

Those assisting should execute their duties quietly, minimizing anxiety-provoking conversation.

Medications

When injecting medications IV through a needle inserted into a port in the IV tubing, the IV should be running fast enough to promptly carry the medication into the patient. It is also important to be certain that the needle is long enough to extend into the main stream of the IV tubing. The following drugs are stocked on the emergency cart in CT at the University of Wisconsin Hospital and Clinics and defined by adult and pediatric dosage:

Adults

- **Albuterol Inhaler:** A Beta-2 agonist that causes bronchodilatation and relieves bronchospasm that may occur with asthma or as a reaction to contrast.

DOSE: 2 puffs to start
May need to be repeated

- **Atropine:** A parasympatholytic agent used to treat bradycardia that results from a vasovagal reaction (characterized by hypotension and bradycardia). The minimum adult dose is 0.6 mg, since a smaller amount can have a paradoxical reverse effect.

DOSE: 0.6–1.0 mg IV slowly
Maximum dose = 2 mg

- **Diphenhydramine:** An antihistamine which is an H-1 receptor site blocker. In this capacity, it blocks circulating histamine from binding to target cells. It does not counteract histamine-mediated reactions that have already begun. Therefore, it should be used only to treat mild urticaria, which is likely to resolve on its own, and where it is deemed desirable to provide symptomatic relief by preventing further reactions. Diphenhydramine should not be used for severe urticaria or other more significant reactions. It does play a role in prophylaxis, as will be discussed.

DOSE: 25–50 mg IV or IM
Caution: Causes drowsiness. Patient should not drive or operate machinery for 4-6 hours.

- **Clonidine:** A drug used to treat a hypertensive crisis.

DOSE: 200 mcg (0.2 mg). Bite, chew, and swallow.

- **Epinephrine:** A drug which is a basic sympathetic agonist with the following effects:

Alpha–Peripheral vasoconstriction

Beta-1–Cardiac: increase contractility and heart rate (chronotropic, inotropic)

Beta-2–Bronchodilatation (bronchioles)

As an alpha agonist, epinephrine is used to treat severe urticaria, facial edema, and laryngeal edema. As a beta-2 agonist, it may be needed to treat bronchospasm. It must be used with caution in patients with cardiac disease and hypertension. Epinephrine is supplied in two strengths: 1:1,000 in 1 mL vials for subcutaneous use, and 1:10,000 in 10 mL prefilled syringes for intravenous use. In each case, 1 mg of epinephrine is supplied. In most cases, the intravenous route is preferred. The subcutaneous route can be used in pediatric patients and in adults when there is inadequate IV access.

DOSE: Subcutaneous: 1:1,000 (1 mg/mL)
0.1–0.3 mL (0.1 – 0.3 mg)

DOSE: Intravenous: 1:10,000 (0.1 mg/mL)
1 mL IV slowly every 3–5 minutes
May repeat up to 1 mg maximum

IMPORTANT: Do NOT use the 1:1000 strength for IV injection.

- **Diazepam:** A benzodiazepine used to treat seizures.

DOSE: 5–10 mg IV push
Maximum dose: 30 mg

- **Nitroglycerin:** A vasodilator used to treat acute angina.

DOSE: 0.4 mg sublingual
May be repeated q 5 minutes for a total of 3 doses

Pediatrics

The overall incidence of adverse reactions in children is less than that in adults. However, children also pose unique problems due to their small size.

It is important to be familiar with pediatric dose regimens. Of note, epinephrine is often administered to children by the subcutaneous route.

The following drugs are stocked on the emergency cart in CT at the University of Wisconsin Hospital and Clinics; the general pediatric dosages are noted below, listed in mg/kg. Laminated cards with exact weight-based dosages are located with the contrast reaction cart. These easy reference cards are convenient for the team during the stress of an acute reaction and also serve to reduce the risk of overmedication.

- **Albuterol:** Inhalant for bronchospasm.

DOSE: 2 puffs --OR--
 2.5 mg in 3 mL normal saline for nebulizer if
 respiratory therapist is present

- **Atropine:** Parasympatholytic agent used to treat bradycardia that occurs in a vasovagal reaction.

DOSE: 0.02 mg/kg IV
 Maximum dose = 1 mg
 Minimum dose = 0.1 mg

- **Diphenhydramine:** Used for treatment of urticaria.

DOSE: 1 mg/kg IV per dose

- **Epinephrine:** Used to treat laryngeal edema, severe urticaria or facial edema, and to supplement Albuterol if needed for bronchospasm.

DOSE: Subcutaneous: 0.01 mg/kg/dose (0.01 mL/kg)
Maximum dose = 0.5 mL

IMPORTANT: Do NOT use the 1:1000 strength for IV injection.

- **Lorazepam:** A benzodiazepine for treatment of seizures.

DOSE: 0.01 mg/kg IV per dose

- **Diazepam:** A benzodiazepine for treatment of seizures

DOSE: 0.2–0.3 mg/kg slow IV push per dose
May repeat in 5-10 minutes

5. NONANAPHYLACTOID REACTIONS

There are three categories of nonanaphylactoid reactions:

- I. Chemotoxic* – organ-specific
 - A.** Nephrotoxicity
 - B.** Cardiovascular toxicity
 - C.** Neurotoxicity
- II. Vasovagal*
- III. Idiopathic*

I. CHEMOTOXIC

A. NEPHROTOXICITY

Physiology

The kidneys receive 20–25 percent of resting cardiac output, approximately 1.2–1.3 liters every minute. Glomerular filtration rate is about 125 mL/min, or 180 liters per day. Urine volume is approximately 1 liter daily, indicating that the kidneys reabsorb more than 99 percent of the glomerular filtrate.

Iodinated contrast agents have a molecular weight in the range of 600–1650 g/mol. From the vascular compartment, they pass through capillaries into the extracellular space. Until eliminated, they remain in the vascular and interstitial compartments, normally entering only cells of the proximal convoluted tubule. Clearance is almost entirely by glomerular filtration. Contrast agents can easily pass through the glomeruli, which can filter molecules up to 40,000 mw.

Pathogenesis

It is well established that iodinated contrast can exert a nephrotoxic effect. Three general types of mechanisms have been described.

1. *Vascular changes.* Primarily a hyperosmotic effect where hypertonic solution in the tubules inhibits water reabsorption, causing the tubules to swell and intrarenal pressure to rise. As a result, both renal blood flow and glomerular filtration decrease.
2. *Tubular injury.* Evidence for a toxic effect is based on observations of reduced clearance of paraaminohippurate under certain conditions and also a rise in the urinary excretion of enzymes found in proximal tubular cells.

3. *Tubular obstruction.* This theory cites older studies that reported precipitation of Bence-Jones proteins with earlier contrast agents, causing tubular obstruction.

Diagnosis of Renal Insufficiency

In most clinical settings, renal function is monitored by serum creatinine, which is not a sensitive marker. Creatinine is a product of muscle metabolism and is therefore proportional to muscle mass. The glomerular filtration rate (GFR) must decline by about 50 percent, to 60 mL/min, before the serum creatinine rises above 1.5 mg/dL. Thus, by the time the serum creatinine becomes abnormal, significant renal dysfunction may already be present.

Therefore, GFR is a more sensitive indicator of renal function than serum creatinine alone. Because creatinine clearance, as derived from 24-hour urine collection, is a cumbersome test and has been shown to overestimate the true GFR by as much as 20% and alternative predictor of GFR is ideal. The estimated GFR (eGFR) is significantly easier to obtain as it is calculated from serum creatinine, age, gender, and ethnicity using the MDRD (Modification of Diet in Renal Disease) calculation. Additionally, eGFR has been shown to be a more accurate predictor of GFR than serum creatinine alone.

There is no universal agreement regarding what value of serum creatinine indicates significant renal insufficiency. However, a level of 1.5 mg/dL is a widely accepted figure. A lower value risks including individuals with normal renal function but a large muscle mass. Choosing a higher value risks excluding individuals who do have renal insufficiency. A serum creatinine of 1.5–3 mg/dL indicates renal insufficiency.

With respect to GFR, moderately decreased renal function is defined as GFR 30-59, severely decreased renal function is defined as GFR 15-29 and renal failure is defined as GFR<15.

Blood urea nitrogen (BUN) is not an adequate measure of renal function. When used in conjunction with serum creatinine, it can provide information about a patient's hydration.

Screening for Renal Disease

While a thorough history is invaluable in evaluating patients for intravenous contrast, screening for underlying renal disease with serum creatinine is also important. Every inpatient requires a serum creatinine measurement within 1 week of the proposed dose of contrast. Outpatients with at least one of the

following risk factors require a serum creatinine measurement within 1 month of the proposed dose of contrast:

1. Age > 65 years
2. Diabetes treated with insulin or other prescribed medication
3. Receiving chemotherapy or aminoglycoside within the past 1 month
4. Diagnosis of a collagen vascular disease
5. Diagnosis of a paraproteinemia syndrome/disease (e.g. multiple myeloma)
6. History of a kidney transplant, renal tumor, renal surgery, or single kidney
7. History of endstage liver disease
8. History of severe congestive heart failure

Of course, these requirements can be waived under appropriate circumstances, such as a life-threatening trauma that requires emergency evaluation. Serum creatinine is not actually a precise marker of renal function, and in cases of doubt a creatinine clearance might be needed.

Renal Toxicity Due to Contrast Agents

Acute renal failure is a clinical entity characterized by an abrupt decline in renal function. Among hospitalized patients, contrast agents have been listed as the third most common cause of acute renal failure for inpatients, behind hypotension and surgery.

Although institutional criteria vary, in general acute renal failure is defined when the serum creatinine raises 25–50 percent or 0.5–1 mg/dL. Serum creatinine peaks in 3–5 days but may be elevated as early as the first day. Clinical manifestations are highly variable and may be absent or proceed to oliguria (< 400 mL/24h). Most effects are temporary and completely reversible. When they are mild, serum creatinine returns to normal in 2 weeks. When severe, dialysis may be necessary.

Predisposing Factors

NORMAL RENAL FUNCTION: For individuals with normal renal function and no additional risk factors, contrast-induced nephrotoxicity is an uncommon event. For these individuals, no significant advantage with regard to acute renal failure has been demonstrated by using LOCM instead of HOVM.

RENAL IMPAIRMENT: For individuals with renal impairment, whether due to intrinsic renal disease or to renal vascular insufficiency, several studies have shown that LOCM agents are less nephrotoxic than HOVM. Adverse effects of contrast agents, moreover, are intensified in DEHYDRATED patients, so it is important to ensure that these patients are adequately hydrated before a contrast study is performed.

DIABETES increases the risk of contrast-induced renal toxicity, even when serum creatinine is normal. The effect is magnified, however, in those patients with both diabetes and renal disease. Additionally, insulin-dependent diabetics are likely at higher risk than non-insulin-dependent diabetics. We arbitrarily set a lower cutoff for the use of IV contrast in diabetics.

The following table contains the current UW guidelines for IV contrast, factoring renal disease and diabetes, according to serum creatinine in mg/dL:

Diabetic

	Creatinine	eGFR
Iohexol	< 1.4	>45
Iodixanol	1.4 – 2.0	45 – 30
No IV Contrast	> 2.0	<30

Non-Diabetic

	Creatinine	eGFR
Iohexol	< 1.8	>30
Iodixanol	1.8 – 3.0	30 – 15
No IV Contrast	> 3.0	<15

Among all predisposing factors, diabetics with pre-existing renal disease constitute the group at highest risk for nephrotoxicity (acute renal failure) from iodinated contrast agents.

PARAPROTEINEMIAS or DYSPROTEINEMIAS are a group of diseases involving the monoclonal production of abnormal immunoglobulin; hence they are also termed MONOCLONAL GAMMOPATHIES. The most important is MULTIPLE MYELOMA; others include Waldenstrom’s macroglobulinemia, heavy chain disease, primary amyloidosis, and monoclonal gammopathy of uncertain significance (MGUS). Most of these patients (except those with heavy chain disease) manifest BENCE-JONES proteins in the urine. These are light chain proteins, either kappa or lambda, that are small enough to be filtered. Old reports of renal failure with HOCM in multiple myeloma documented tubular obstruction due to precipitated Bence-Jones proteins. More recently, it has been postulated that such precipitation is not likely with the newer classes of agents, if patients are not dehydrated. If an iodinated contrast study is needed in such a patient, adequate hydration and a LOCM are mandatory.

TAMM-HORSEFALL proteins are produced by cells in the ascending Loop of Henle. With low flow, they form hyaline casts of the tubules that appear in the urine. In patients with normal renal function, they signify only dehydration. When renal disease is present, red blood cells pass through the damaged glomerulus, become enmeshed in the Tamm-Horsefall protein precipitate, and appear as red

cell casts. They are laboratory indicators of renal injury, but are not employed directly to determine the use of contrast agents.

GOUT (a disease arising from hyperuricemia) affects the kidneys by precipitation of uric acid crystals in acid urine (acute urate nephropathy) or by formation of sodium urate tophi in renal parenchyma (chronic urate nephropathy).

Hyperuricemia was implicated in early studies as a cause of acute renal failure in iodinated contrast nephrotoxicity, but it has never been proven to be a stand-alone factor. Nonetheless, it continues to be seen as a relative risk factor, and if the contrast study cannot be postponed, patients with acute gout must at least be adequately hydrated. With the added presence of renal insufficiency (serum creatinine > 1.5 mg /dL), an alternative study should be considered.

METFORMIN (GLUCOPHAGE™) is an oral antihyperglycemic medication used to treat diabetes. It is eliminated unchanged through the kidneys, likely by glomerular filtration and tubular excretion. As a biguanide, it stimulates intestinal production of lactic acid.

Lactic acidosis can be fatal. Conditions that reduce metformin excretion or increase serum lactate include:

1. Renal disease—decreases metformin excretion
2. Liver disease—decreases lactic acid metabolism
3. Heart disease—increases anaerobic metabolism

Accordingly, in order to avoid lactic acidosis due to acute renal failure, the following precautions should be taken:

1. Metformin should be withheld at the time iodinated contrast is used.
2. It may be resumed in 48 hours only if renal function is shown to be normal.

B. CARDIOVASCULAR TOXICITY

Patients with underlying cardiac disease have an increased incidence and/or severity of cardiovascular side effects. Pulmonary angiography and intracardiac and coronary artery injections carry the highest degree of risk. Possible reactions include hypotension, tachycardia, and arrhythmias. More severe, but uncommon reactions include congestive heart failure, pulmonary edema, and cardiac arrest.

C. NEUROTOXICITY

Iodinated contrast agents cause a change in the blood-brain barrier due to their hypertonicity. These risks are reduced when low or iso-osmolar agents are used. Potential reactions include headache, confusion, seizures, altered consciousness, visual disturbances, and dizziness.

II. VASOVAGAL REACTIONS

Vasovagal reactions are characterized by bradycardia and hypotension.

Initial resuscitation should include elevating the legs and/or placing the patient in a Trendelenburg position and administering O₂ at the rate of 6–10 liters/minute.

Atropine may be used in the initial treatment of bradycardia. Epinephrine may be necessary. See section on treatment of anaphylactoid reactions for appropriate doses.

IV fluids are used to treat hypotension and should be administered rapidly. Large volumes may be required. Normal saline and Ringer's lactate are appropriate choices.

It is important to monitor vital signs frequently to titrate the amount of medications and fluids that are used.

6. RISK FACTORS

There are certain diseases or conditions that place a patient at added risk for an adverse reaction to contrast. It is important that they be recognized in order that appropriate precautionary measures and safeguards may be taken. To this end, a careful and accurate history and review of pertinent lab data are vital.

Age—This is not an important factor in and of itself. However, it should be remembered that significant illness is common among the elderly. Additionally, they may have decreased reserve that makes them less able to tolerate a reaction.

Allergies—A history of allergies doubles the risk of an adverse reaction.

Anxiety—It has long been recognized that there is an increase in both the rate and the severity of contrast reactions in anxious or fearful patients. Therefore it is important that all medical personnel involved in a contrast procedure, and especially the radiologist, conduct themselves in a manner that bespeaks calmness, self-assurance, and competence, one that calms patients and allays fears. It may be necessary to premedicate some patients. At the University of

Wisconsin Hospital and Clinics, midazolam 2 mg IV titrated up to a 5 mg maximum dose is recommended (note this is contraindicated in patients with glaucoma).

Asthma—A history of allergic asthma increases the risk of reaction up to five times.

Cardiac Disease—Severe cardiac disease carries an increased risk of reaction. Pertinent conditions include congestive heart failure, angina, cardiomyopathy, aortic valvular disease, and pulmonary hypertension. Whenever possible, the total dose of contrast should be reduced.

Debility—Debilitated patients are at added risk of adverse reaction due to decreased ability to cope with the chemotoxicity of contrast agents.

Dehydration—Dehydration has the potential to increase nephrotoxicity, particularly in patients with impaired renal function or multiple myeloma. If it is absolutely necessary for a patient with multiple myeloma, sickle cell disease, homocystinuria, or gout to receive iodinated contrast, it is imperative that the individual be adequately hydrated prior to the scan.

Diabetes—See section on nephrotoxicity.

Dialysis—Patients who are on dialysis for potentially reversible acute renal failure may receive iodinated contrast if deemed necessary by the referring physician. It seems that the insult to the renal parenchyma occurs during the first pass of contrast. Therefore, the current opinion is that the timing of hemodialysis, with respect to contrast administration, is irrelevant. Rather, it is more important to ensure that the patient is adequately hydrated prior to contrast administration.

Patients who are on routine hemodialysis for end-stage renal disease can receive non-ionic contrast. It is not imperative that dialysis be performed immediately following the contrast procedure. However, it is preferable that the study be scheduled so that the next routine dialysis is within 24 hours following the examination.

Gout— See section on nephrotoxicity. If a contrast-enhanced examination is absolutely necessary in a patient with acute gout, the individual must be well hydrated.

Interleukin-2 Immunotherapy—Individuals who are on interleukin-2 or who have taken it in the past, as long as 2 years previously, are at risk for delayed reactions occurring several hours after the injection, similar to those that occur with interleukin-2 itself. University of Wisconsin Hospital and Clinics guidelines require that patients be monitored for 2 hours after the examination has been completed.

Metformin (Glucophage)—See section on nephrotoxicity. Patients who receive iodinated contrast may not resume metformin for 48 hours after the iodinated contrast injection.

Multiple Myeloma—See section on nephrotoxicity. If these patients absolutely must have iodinated contrast, they must be well hydrated.

Pheochromocytoma—Patients with pheochromocytoma are at risk for a hypertensive crisis during the administration of contrast. Blood pressure must be carefully monitored. University of Wisconsin Hospital and Clinics protocol requires baseline blood pressure and pulse recordings and subsequent checks just after injection and then every 5 minutes for 30 minutes or until it is deemed safe to stop.

Previous Contrast Reaction—Without premedication (see section on Premedication), the risk of reaction is increased from 3 to 8 times.

Sickle Cell Disease—If iodinated contrast is absolutely necessary, these patients must be adequately hydrated.

7. EXTRAVASATION OF CONTRAST

Extravasation of small amounts of contrast usually results in only minimal symptoms, including swelling, erythema, and pain. These symptoms usually abate with no lasting effect.

Depending on the agent used, severe reactions can occur. They take the form of skin ulceration and necrosis. The primary underlying mechanism is believed to be the hyperosmolality of the contrast agent. Mechanical compression due to a compartment syndrome may also occur. The following factors increase the severity of reactions:

1. Vascular insufficiency—arterial, venous, lymphatic.
2. Type of contrast agent—ionic more harmful than nonionic.
3. Volume of extravasation; depending on location, significant reactions can occur from even small volumes (< 10 mL).
4. Dorsum of hand, foot, and ankle where there is less subcutaneous tissue or where nerves and vessels are near.

The inflammatory reaction usually reaches a maximum in 24–48 hours.

Recommendations for observation and treatment vary, although each institution should develop its own protocol. A summary of the protocol currently in place in the University of Wisconsin Hospital and Clinics policy is as follows:

1. Immediate cessation of injection when a problem is detected.
2. Notification of responsible physicians.
3. Initial treatment—Elevation of the affected extremity, warm or cold packs, observation, notification of referring physician if volume > 50 mL. Intermittent, brief compression to milk the extravasate centrally can be applied with an ace wrap. (DO NOT leave the wrap on for more than 1 minute to avoid compartment syndrome.) Some authors recommend the application of heat; others—cold. The issue of hot vs. cold compress has little relevance in the case of LOCM.
4. Indications for plastic surgery consultation include any one of the following: Volume > 100 mL (or less if appropriate), blisters, decreased capillary refill, increased pain after 2–4 hours, changes in sensation.
5. Instructions are given to the patient.
6. Follow-up calls.
7. Documentation.

8. PREMEDICATION

Overall, patients who are at added risk for an anaphylactoid reaction benefit from premedication. Such patients include those with asthma, allergies, or a history of a prior moderate or severe reaction to contrast. It should be noted, however, that premedication is not a 100 percent guarantee that an iodinated contrast-enhanced examination can be safely performed.

The premedication regimen at the University of Wisconsin Hospitals and Clinics includes:

1. Methylprednisolone:
DOSE: 32 mg by mouth 12 and 2 hours before contrast.
2. Diphenhydramine
DOSE:
 - a. 50 mg IM or PO 1 hour before contrast, OR
 - b. 50 mg (or 25 mg per height/weight indication) IV 15–20 minutes before contrast.

Note: Patients may not drive or operate heavy machinery for 4–6 hours after receiving diphenhydramine.

In addition, these patients should receive nonionic contrast agents.

9. CONCLUSIONS

Although contrast agents are widely used with safe outcomes and little or no side effects, adverse reactions nonetheless may occur. They may be severe, and they may progress rapidly. Successful patient management during contrast-enhanced examinations requires all of the following:

1. Knowledge of the patient's medical history.
2. Patient preparation, including premedication, if necessary.
3. Proper selection of the agent to be used.
4. Knowledge of the pathophysiology of contrast reactions.
5. Prompt recognition and accurate assessment of reactions.
6. Immediate availability of necessary equipment and drugs.
7. Adequate prior planning and training.
5. Current knowledge of medications and other treatment options.

In summary, vigilance and attention to detail are key. Expect the unexpected and be prepared.

10. APPENDIX: GENERIC AND TRADE NAMES OF DRUGS AND CONTRAST AGENTS

Note: The trade names listed here are examples of ones commonly in use; other trade name products may also be available.

<u>Generic Names</u>	<u>Trade Names</u>
Albuterol.....	Proventil
Diazepam.....	Valium
Diphenhydramine.....	Benadryl
Iodixanol.....	Visipaque
Iohexol.....	Omnipaque
Metformin.....	Glucophage
Metaproterenol.....	Alupent
Methylprednisolone.....	Medrol
